Table 1. The Performance of AES-128 in GCM Mode (on a processor based on Intel microarchitecture codename Westmere) ................................................. 73
Introduction

PCLMULQDQ is a new processor instruction that Intel is introducing in the 2010 Intel® Core™ processor family based on the 32nm Intel® microarchitecture codename Westmere, entering production starting the end of 2009. It computes the carry-less product of two 64-bit operands.

This paper provides details the PCLMULQDQ instruction, and describes several algorithms for using it for computing the Galois Hash, which is the underlying computation of the Galois Counter Mode (GCM).

An important usage model is AES in Galois counter Mode (AES-GCM), where the AES encryption/decryption part can be implemented efficiently using the Intel AES New Instructions which are also being introduced (see Reference [17], http://software.intel.com/en-us/articles/advanced-encryption-standard-aes-instructions-set/ for details). This paper provides code examples for AES-GCM, using the new instructions, and also discloses their resulting performance.

This version of the paper provides high performance code examples for AES-GCM, and discloses, for the first time, their measured performance numbers.

Preliminaries

Usage Models of Carry-less Multiplication

Carry-less multiplication is the mathematical operation of computing the (carry-less) product of two operands without the generation or propagation of carry values. It is a relatively time consuming operation when implemented with the current ISA of the IA architecture. For example, software implementation of carry-less multiplication that uses one of the best-known methods (found at the OpenSSL source code distribution, www.openssl.org) computes a 64 by 64 bit carry-less product in about 100 cycles.

Carry-less multiplication is an essential processing component of several cryptographic systems and standards. Hence, accelerating carry-less multiplication can significantly contribute to achieving high speed secure computing and communication. Carry-less multiplication is especially important for implementing the Galois Counter Mode (GCM), which is a recently defined mode of operation of block ciphers [4, 6, 7, 8, 14, 15]. The GCM mode was endorsed by the US government in April 2006 and is used together with AES, which is part of the NSA Suite B. It is also defined in IEEE 802.1ae standard, where it is recommended for forwarding rates higher than 10 Gbps. Other usage models of GCM include IPsec (IPsec RFC 4106), the storage standard P1619 and security protocols over fiber channel (ISO-T11 standard).

GCM performs carry-less multiplication of 128-bit operands, producing a 255-bit product. This is the first step of computing a ‘Galois hash’, which is part of the GCM mode. The PCLMULQDQ instruction computes the 127-bit product of two 64-bit operands. It can be used by software as a building block for generating the 255-bit result required for GCM.
The other step in GCM is reduction modulo of a pentanomial $x^{128} + x^7 + x^2 + x + 1$. In this document, we describe a new efficient algorithm for performing this reduction in the Intel® SSE domain (using PSRLD, PSLLD, PSHUFD instructions). The combination of the PCLMULQDQ instruction, together with this algorithm speeds up the GCM mode.

Carry-less multiplication is also in the core computation of Elliptic Curve Cryptography (ECC) over binary fields [2] and Cyclic Redundancy Checks (CRCs). The carry-less multiplication instruction PCLMULQDQ can speedup the computation of CRC with polynomials other than the ISCSI polynomial, for which there is already a dedicated instruction in the ISA (namely, CRC32 that is part of the Intel SSE4 set).

### Carry-Less Multiplication - Definition

Carry-less multiplication is the operation of multiplying two operands without generating and propagating carries. It is formally defined as follows. Let the two operands $A$, $B$, be defined by the following $n$-bit array notation

$$A = [a_{n-1} \ a_{n-2} \ ... \ a_0], \ B = [b_{n-1} \ b_{n-2} \ ... \ b_0] \quad (1)$$

and let the carry-less multiplication result be the following $2n-1$ bit array:

$$C = [c_{2n-2} \ c_{2n-2} \ ... \ c_0] \quad (2)$$

The bits of the output $C$ are defined as the following logic functions of the bits of the inputs $A$ and $B$ as follows:

$$c_i = \bigoplus_{j=0}^{i} a_j b_{i-j} \quad (3)$$

for $0 \leq i \leq n-1$, and

$$c_i = \bigoplus_{j=-n+1}^{n-1} a_j b_{i-j} \quad (4)$$

for $n \leq i \leq 2n-2$.

One can see that the logic functions of Equations (3) and (4) are somehow analogous to integer multiplication in the following sense. In integer multiplication, the first operand is shifted as many times as the positions of bits equal to "1" in the second operand. The integer multiplication is obtained by adding the shifted versions of the first operand with each other. The same procedure is followed in carry-less multiplication, but the "additions" do not generate or propagate carry, and are equivalent to the exclusive OR (XOR) logical operation.

Hereafter, carry-less multiplication is denoted by the symbol "•".
Carry-less Multiplication and Galois Field Multiplication

Typically, carry-less multiplication is used as the first step of multiplications in finite fields (aka Galois Fields) of characteristic 2 [10, 11, 12, 13].

A Galois Field is a finite set of elements where the operations addition `+` and multiplication `·` are defined. The set is closed under these operations where they satisfy the following properties: associativity, commutativity, existence of a neutral element (for addition it is called “0” and for multiplication it is called “1”), existence of additive inverse, existence of multiplicative inverse for each element except for zero, and a distributive law for multiplication over addition (i.e., \( a \cdot (b+c) = a \cdot b + a \cdot c \)).

The number of elements of a finite field must be a power of some prime \( p \), where in such case the field is denoted by \( GF(p^k) \). A binary field (field with characteristic 2) is the case where \( p=2 \), and is denoted by \( GF(2^k) \).

In general, the elements in \( GF(p^k) \) can be viewed as polynomials of degree \( k \) where the operations are defined using some irreducible polynomial of degree \( k \): addition of two elements is defined as polynomial addition (adding the corresponding coefficients modulo \( p \)). Multiplication is defined by polynomial multiplication, which is subsequently reduced modulo the irreducible polynomial that defines the finite field.

Typically, there are multiple different irreducible polynomials of degree \( k \). Using them to define the finite field results in isomorphic representations of the field.

For binary fields \( GF(2^n) \), one can view the elements as \( n \)-bit strings, where each bit represents the corresponding coefficient of the polynomial. In such cases, addition is equivalent to the bitwise XOR of the two strings. Multiplication consists of two steps. The first step is carry-less multiplication of the two operands. The second step is the reduction of this carry-less product modulo the polynomial that defines that field.

For example, consider the field \( GF(2^4) \) (i.e., \( n=4 \)) defined by the reduction polynomial \( x^4+x+1 \). Let \( A = [1110] \) and \( B = [1011] \) be two elements in that field. Then, their product in this field is \([1000]\). This result is obtained as follows: Performing the carry-less multiplication \( C = A \cdot B \) results in \([01100010]\). This is followed by reducing \( C \) modulo \( x^4+x+1 \). The reduction result is obtained by finding that \([01100010] = [0110] \cdot [1001] \) XOR \([1000]\).

PCLMULQDQ Instruction Definition

PCLMULQDQ instruction performs carry-less multiplication of two 64-bit quadwords which are selected from the first and the second operands according to the immediate byte value.

<table>
<thead>
<tr>
<th>Instruction format</th>
<th>PCLMULQDQ xmm1, xmm2/m128, imm8</th>
</tr>
</thead>
</table>

**Description:** Carry-less multiplication of one quadword (8 bytes) of xmm1 by one quadword (8 bytes) of xmm2/m128, returning a double quadword (16 bytes). The immediate byte is used for determining which quadwords of
xmm1 and xmm2/m128 should be used.

**Opcode:** 66 0f 3a 44

The presence of PCLMULQDQ is indicated by the CPUID leaf 1 ECX[1]. Operating systems that support the handling of Intel SSE state will also support applications that use AES extensions and the PCLMULQDQ instruction. This is the same requirement for Intel SSE2, Intel SSE3, Intel SSSE3, and Intel SSE4.

The immediate byte values are used as follows.

<table>
<thead>
<tr>
<th>imm[7:0]</th>
<th>Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x00</td>
<td>xmm2/m128[63:0] • xmm1[63:0]</td>
</tr>
<tr>
<td>0x01</td>
<td>xmm2/m128[63:0] • xmm1[127:64]</td>
</tr>
<tr>
<td>0x10</td>
<td>xmm2/m128[127:64] • xmm1[63:0]</td>
</tr>
<tr>
<td>0x11</td>
<td>xmm2/m128[127:64] • xmm1[127:64]</td>
</tr>
</tbody>
</table>

**NOTE:**
1. The symbol "•" denotes carry-less multiplication
2. Immediate bits other than 0 and 4 are ignored.

The pseudo code for defining the operation is as follows.

```plaintext
IF imm8[0] == 0 THEN
    Temp1 = xmm1[63:0]
ELSE
    Temp1 = xmm1[127:64]
ENDIF
IF imm8[4] == 0 THEN
    Temp2 = xmm2/m128[63:0]
ELSE
    Temp2 = xmm2/m128[127:64]
ENDIF
FOR i = 0 TO 63
    TempB [i] := (Temp1[0] AND Temp2[i]);
    FOR j = 1 TO i, 1
        TempB [i] := TempB [i] XOR (Temp1[j] AND Temp2[i - j])
    NEXT j
    Dest[i] := TempB[i];
NEXT i
FOR i = 64 TO 126, 1
    TempB [i] := (Temp1[ i-63] AND Temp2[63]);
    FOR j = i-62 TO 63, 1
```
TempB [i] := TempB [i] XOR (Temp1[j] AND Temp2[i - j])
NEXT j
Dest[i] := TempB [i];
NEXT i
Dest[127] := 0;

The AVX (Nondestructive Destination) Variant
VPCLMULQDQ

The carry-less multiplication instruction PCLMULQDQ has a nondestructive version (VEX.128 encoded version), namely, VPCLMULQDQ, which is defined as follows.

**Instruction format:** VPCLMULQDQ xmm1, xmm2, xmm3/m128, imm8

**Description:** Carry-less multiplication of one quadword of xmm2 by one quadword of xmm3/m128, returning a double quadword (16 bytes) in register xmm1. The immediate is used for determining which quadwords of xmm2 and xmm3/m128 should be carry-less multiplied. The immediate byte is used exactly as in PCLMULQDQ. Functionally, this provides a non-destructive variant of PCLMULQDQ.

**Opcode:** VEX.NDS.128.66.0F3A 44 /r ib

The presence of VPCLMULQDQ is indicated by CPUID leaf 1 ECX[1].

The instruction operates on xmm states. The detection sequence must combine checking for CPUID.01H:ECX.PCLMULQDQ[bit 1] = 1, and the sequence for detection application support for GSSE.

Bits (255:128) of the destination ymm register are zeroed.

Identifying PCLMULQDQ Support by the Processor

Before an application attempts to use the PCLMULQDQ instruction it should check for its availability, which is indicated if CPUID.01H:ECX.PCLMULQDQ[bit 1] = 1.

Operating systems that support handling Intel® SSE state support also applications that use PCLMULQDQ. This is the same requirement for Intel SSE2, Intel SSE3, Intel SSSE3, and Intel SSE4.

The Galois Counter Mode (GCM)

This section described the Galois Counter Mode and its current lookup table based software implementation (see for example [5] and www.openssl.org).
The Definition of GCM

The Galois Counter Mode is illustrated in Figure 1. This mode produces a message digest, called “Galois Hash™”, from the encrypted data. This Galois Hash is used for high performance message authentication. In each step of the mode, the previous Galois Hash value is XOR-ed with the current ciphertext block. The result is then multiplied in GF(2^{128}) with a hash key value. GCM uses GF(2^{128}) defined by the irreducible polynomial \( g(x) = x^{128} + x^7 + x^2 + x + 1 \).

**Figure 1. The Galois Counter Mode**

<table>
<thead>
<tr>
<th>block Cipher</th>
<th>data 1</th>
<th>data 2</th>
<th>data 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>ciphertext 1</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>⊕</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Galois Counter Mode</td>
<td>multiply with hash key in GF(2^{128})</td>
<td>multiply with hash key in GF(2^{128})</td>
<td>etc…</td>
</tr>
<tr>
<td>hash 0</td>
<td></td>
<td>hash 1</td>
<td></td>
</tr>
<tr>
<td></td>
<td>⊕</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>hash 2</td>
<td></td>
</tr>
</tbody>
</table>

The multiplication in GF(2^{128}) involves carry-less multiplication of two 128-bit operands, to generate a 255-bit result (or, equivalently, 256-bit result, where the most significant bit equals 0), followed by and reduction modulo the irreducible polynomial \( g \).

Current Software Implementation of GCM

Some of the current software implementations of GCM implement the Galois Field multiplication directly. Such implementations are not very efficient when using only the current IA instructions set. One example is given in Figure 2, taken from OpenSolaris. Solaris has C function gcm_mul() that takes two 64-bit elements (*x_in and *y in Figure 2), and places their carryless product in a third 64-bit integer (*res). Figure 2 is the current C source code from [http://src.opensolaris.org/source/xref/onnv/onnv-gate/usr/src/common/crypto/modes/gcm.c#46](http://src.opensolaris.org/source/xref/onnv/onnv-gate/usr/src/common/crypto/modes/gcm.c#46) (Copyright 2009 Sun Microsystems, Inc.)
Figure 2. The OpenSolaris “gfmul” C Function

/* copied from http://src.opensolaris.org/source/xref/onnv/onnv-gate/usr/src/common/crypto/modes/gcm.c#46

#include <stdint.h>
#include <wmmintrin.h>
struct aes_block {
    uint64_t a;
    uint64_t b;
};
void gfmul(__m128i x_in_m, __m128i y_m, uint64_t *res) {
    uint64_t R = { 0xe100000000000000ULL };
    struct aes_block z = { 0, 0 };
    struct aes_block v;
    uint64_t x;
    int i, j;
    uint64_t *x_in=(uint64_t*)&x_in_m;
    uint64_t *y=(uint64_t*)&y_m;
    v.a=y[1];
    v.b=y[0];
    for (j = 1; j>=0; j--) {
        x = x_in[j];
        for (i = 0; i < 64; i++, x <<= 1) {
            if (x & 0x8000000000000000ULL) {
                z.a ^= v.a;
                z.b ^= v.b;
            }
            if (v.b & 1ULL) {
                v.b = (v.a << 63)|(v.b >> 1);
                v.a = (v.a >> 1) ^ R;
            } else {
                v.b = (v.a << 63)|(v.b >> 1);
                v.a = v.a >> 1;
            }
        }
    }
    res[0] = z.b;
    res[1] = z.a;
}

A more optimized software implementations of the GCM mode use a lookup table based algorithm [5], shown in Figure 3 (for AES-GCM). The pseudo-code of Figure 3 does not take into account bit and byte reflection peculiarities of GCM implementations. This algorithm consists of two phases:

**Preprocessing phase:** generation of 16 lookup tables. Each table has 256 128-bit entries where entry \( j \) of table \( T_i \) stores the value \((j \times \text{hash key} \times 2^{28}) \mod g\) for \( j = 0, 1, \ldots, 255\), and \( i = 0, 1, \ldots, 15\).
Run time phase: The algorithm takes the next ciphertext block and XOR-s it with the current value of the Galois Hash. The result (dynamic value) is multiplied with the Hash Key (fixed value) in GF(2^{128}). The GF(2^{128}) multiplication is carried out as follows: the value of the result is segmented into 16 8-bit slices. Subsequently, 16 table lookups are performed, using the slices, for indexing the tables. The results from the table lookups are XOR-ed with each other.

This algorithm performs operations on a per-byte basis: each 128-bit block involves 16 table lookups and 16 128-bit XOR operations.

This algorithm is not very efficient in software due to the cost of table lookups. It also suffers from potential side channel leakage based on memory access patterns (the accessed cache lines for the table lookup are data dependent).

Figure 3. Lookup Table Based Implementation of AES-GCM

    for(j=0; j < 16; j++)
        xor128(temp, tables[j][bytes_gh[j]]);
    // tables[i][j] = j*hash_key*256*i mod x^128 + x^7 + x^2 + x + 1
    copy128(galoishash, temp);
}
Efficient Algorithms for Computing GCM

This section describes several new methods for computing the Galois Counter Mode. This method is an extension of the algorithm described in [6, 7].

The method described here uses the 64-bit PCLMULQDQ instruction in place of the lookup table method, for computing 128-bit-by-128-bit carry-less products, and an efficient novel method for reducing the result modulo the irreducible polynomial $g$ of the finite field GF($2^{128}$). The proposed algorithms are carried out in two steps: carry-less multiplication and reduction modulo $g = x^{128} + x^7 + x^2 + x + 1$.

Performing Carry-less Multiplication of 128-bit Operands Using PCLMULQDQ

Denote the input operands by $[A_1:A_0]$ and $[B_1:B_0]$, where $A_0$, $A_1$, $B_0$ and $B_1$ are 64 bit long each.

The following algorithm can be viewed as “one iteration carry-less schoolbook” multiplication.

**Algorithm 1**

**Step 1:** multiply carry-less the following operands: $A_0$ with $B_0$, $A_1$ with $B_1$, $A_0$ with $B_1$, and $A_1$ with $B_0$. Let the results of the above four multiplications be:

$A_0 \cdot B_0 = [C_1:C_0]$, $A_1 \cdot B_1 = [D_1:D_0]$, $A_0 \cdot B_1 = [E_1:E_0]$, $A_1 \cdot B_0 = [F_1:F_0]$  

**Step 2:** construct the 256-bit output of the multiplication $[A_1:A_0] \cdot [B_1:B_0]$ as follows:

$[A_1:A_0] \cdot [B_1:B_0] = [D_1 : F_1 \oplus E_1 \oplus D_0 : F_0 \oplus E_0 \oplus C_1 : C_0]$  

(5)

An alternative technique trades-off one multiplication for additional XOR operations. It can be viewed as “one iteration carry-less Karatsuba” multiplication [7, 9].

**Algorithm 2**

**Step 1:** multiply carry-less the following operands: $A_1$ with $B_1$, $A_0$ with $B_0$, and $A_0 \oplus A_1$ with $B_0 \oplus B_1$. Let the results of the above three multiplications be: $[C_1:C_0]$, $[D_1:D_0]$ and $[E_1:E_0]$, respectively.

**Step 2:** construct the 256-bit output of the multiplication $[A_1:A_0] * [B_1:B_0]$ as follows:

$[A_1:A_0] * [B_1:B_0] = [C_1 : C_0 \oplus C_1 \oplus D_1 \oplus E_1 : D_1 \oplus C_0 \oplus D_0 \oplus E_0 \oplus D_0]$  

(6)

Efficient Reduction Algorithm

To reduce a 256-bit carry-less product modulo a polynomial $g$ of degree 128, we first split it into two 128-bit halves. The least significant half is simply XOR-ed with the final remainder (since the degree of $g$ is 128).
For the most significant part, we develop an algorithm that realizes division via two multiplications. This algorithm can be seen as an extension of the Barrett reduction algorithm [1] to modulo-2 arithmetic, or as an extension of the Feldmeier CRC generation algorithm [3] to dividends and divisors of arbitrary size.

Since we do not need to take into account the least significant half of the input (see above), we investigate the efficient generation of a remainder \( p(x) \) defined as follows:

\[
p(x) = c(x) \cdot x' \mod g(x)
\]

Where,

1. \( c(x) \) is a polynomial of degree \( s-1 \) with coefficients in GF(2), representing the most significant bits of the carry-less product. (for GCM, \( s = 128 \)).
2. \( t \) is the degree of the polynomial \( g \). (for GCM, \( t = 128 \)).
3. \( g(x) \) is the irreducible polynomial defining the final field (for GCM, \( g = x^{128} + x^7 + x^2 + x + 1 \)).

For the polynomials \( p(x), c(x), \) and \( g(x) \) we write:

\[
c(x) = c_{s-1}x^{s-1} + c_{s-2}x^{s-2} + \ldots + c_1x + c_0,
\]

\[
p(x) = p_{t-1}x^{t-1} + p_{t-2}x^{t-2} + \ldots + p_0x + p_0, \text{ and}
\]

\[
g(x) = g_tx^t + g_{t-1}x^{t-1} + \ldots + g_0x + g_0
\]

Hereafter, we use the notation \( L^u(v) \) to denote the coefficients of the \( u \) least significant terms of the polynomial \( v \) and \( M^u(v) \) to denote the coefficients of its \( u \) most significant terms. The polynomial \( p(x) \) can be expressed as:

\[
p(x) = c(x) \cdot x' \mod g(x) = g(x) \cdot q(x) \mod x'
\]

where \( q(x) \) is a polynomial of degree \( s-1 \) equal to the quotient from the division of \( c(x) \cdot x' \) with \( g \). The intuition behind equation (9) is that the \( t \) least significant terms of the dividend \( c(x) \cdot x' \) equal zero. Further, the dividend \( c(x) \cdot x' \) can be expressed as the sum of the polynomials \( g \cdot q \) and \( p \):

\[
c(x) \cdot x' = g(x) \cdot q(x) + p(x)
\]

where operator '+' means XOR (‘⊕’). From equation (10) one can expect that the \( t \) least significant terms of the polynomial \( g \cdot q \) are equal to the terms of the polynomial \( p \). Only if these terms are equal to each other, the result of the XOR operation \( g \cdot q \oplus p \) is zero for its \( t \) least significant terms. Hence:

\[
p(x) = g(x) \cdot q(x) \mod x' = L'(g(x) \cdot q(x))
\]

Now we define

\[
g(x) = g_tx^t + g^*(x)
\]
The polynomial $g^*$ represents the $t$ least significant terms of the polynomial $g$. Obviously,

$$p(x) = L'(g(x) \cdot q(x)) = L'(q(x) \cdot g^*(x) + q(x) \cdot g \cdot x')$$

(13)

However, the $t$ least significant terms of the polynomial $q \cdot g \cdot x'$ are zero. Therefore,

$$p(x) = L'(q(x) \cdot g^*(x))$$

(14)

From Equation (14) it follows that in order to compute the remainder $p$ we need to know the value of the quotient $q$. The quotient can be calculated in a similar manner as in the Barrett reduction algorithm:

$$(9) \iff c(x) \cdot x'^s = g(x) \cdot q(x) \cdot x^s + p(x) \cdot x^s$$

(15)

Let

$$x'^s = g(x) \cdot q'^s(x) + p^s(x)$$

(16)

where $q^s$ is an $s$-degree polynomial equal to the quotient from the division of $x'^s$ with $g$ and $p^s$ is the remainder from this division. The degree of the polynomial $p^s$ is $t-1$. From equations (15) and (16) we get

$$\begin{align*}
(15) \iff & c(x) \cdot g(x) \cdot q^s(x) + c(x) \cdot p^s(x) \\
(16) \iff & = g(x) \cdot q(x) \cdot x^s + p(x) \cdot x^s
\end{align*}$$

(17)

and

$$\begin{align*}
(17) \implies M^s(c(x) \cdot g(x) \cdot q^s(x) + c(x) \cdot p^s(x)) \\
& = M^s(g(x) \cdot q(x) \cdot x^s + p(x) \cdot x^s)
\end{align*}$$

(18)

One can see that the polynomials $c \cdot g \cdot q^s$ and $g \cdot q \cdot x^s$ are of degree $t+2 \cdot s-1$ the polynomial $c \cdot p^s$ is of degree $t+s-2$, and the polynomial $p \cdot x^s$ is of degree $t+s-1$. As a result the $s$ most significant terms of the polynomials in the left and right hand side of equation (18) are not affected by the polynomials $c \cdot p^s$ and $p \cdot x^s$. Hence,

$$\begin{align*}
(18) \iff & M^s(c(x) \cdot g(x) \cdot q^s(x)) \\
& = M^s(g(x) \cdot q(x) \cdot x^s)
\end{align*}$$

(19)

Next, we observe that the $s$ most significant terms of the polynomial $c \cdot g \cdot q^s$ equal to the $s$ most significant terms of the polynomial $g \cdot M^s(c \cdot q^s) \cdot x^s$. The polynomial $M^s(c \cdot q^s) \cdot x^s$ results from $c \cdot q^s$ by replacing the $s$ least significant terms of this polynomial with zeros. The intuition behind this observation is the following: the $s$ most significant terms of the polynomial $c \cdot g \cdot q^s$ are calculated by adding the $s$ most significant terms of the polynomial $c \cdot q^s$ with each other in as many offset positions as defined by the terms of
the polynomial \( g \). Thus, the \( s \) most significant terms of \( c \cdot g \cdot q^+ \) do not depend on the \( s \) least significant terms of \( c \cdot q^+ \), and consequently,

\[
(19) \iff M^s(g(x) \cdot M^s(c(x) \cdot q^+(x)) \cdot x^s) = M^s(g(x) \cdot q(x) \cdot x^s) \tag{20}
\]

Equation (20) is satisfied for \( q \) given by

\[
q = M^s(c(x) \cdot q^+(x)) \tag{21}
\]

Since there is a unique quotient \( q \) satisfying equation (10) one can show that there is a unique quotient \( q \) satisfying equation (20). As a result this quotient \( q \) must be equal to \( M^s(c(x) \cdot q^+(x)) \).

It follows that the polynomial \( p \) is found by

\[
p(x) = L^t(g^*(x) \cdot M^s(c(x) \cdot q^+(x))) \tag{22}
\]

Equation (22) indicates the algorithm for computing the polynomial \( p \).

**Algorithm 3:**

**Preprocessing:** For the given irreducible polynomial \( g \) the polynomials \( g^* \) and \( q^+ \) are computed first. The polynomial \( g^* \) is of degree \( t-1 \) consisting of the \( t \) least significant terms of \( g \), whereas the polynomial \( q^+ \) is of degree \( s \) and is equal to the quotient of the division of \( x^t + s \) with the polynomial \( g \).

**Calculation of the remainder polynomial:**

**Step 1:** The input \( c \) is multiplied with \( q^+ \). The result is a polynomial of degree \( 2s-1 \).

**Step 2:** The \( s \) most significant terms of the polynomial resulting from step 1 are multiplied with \( g^* \). The result is a polynomial of degree \( t+s-2 \).

**Step 3:** The algorithm returns the \( t \) least significant terms of the polynomial resulting from step 2. This is the desired remainder.

**Application of the method for reduction modulo \( x^{128} + x^7 + x^2 + x + 1 \)**

One can see that the quotient from the division of \( x^{256} \) with \( g \) is \( g \) itself. The polynomial \( g = g(x) = x^{128} + x^7 + x^2 + x + 1 \) contains only 5 non-zero coefficients (therefore also called “pentanomial”). This polynomial can be represented as the bit sequence \([1:<120 \text{ zeros}>:10000111]\). Multiplying this carry-less with a 128-bit value and keeping the 128 most significant bit can be obtained by: (i) Shifting the 64 most significant bits of the input by 63, 62 and 57-bit positions to the right. (ii) XOR-ing these shifted copies with the 64 least significant bits of the input. Next, we carry-less multiply this 128-bit result with \( g \), and keep the 128 least significant bits. This can be done by: (i) shifting the 128-bit input by 1, 2 and 7 positions to the left. (ii) XOR-ing the results. Algorithm 4 provides a detailed description of the reduction algorithm.

**Algorithm 4**
Denote the input operand by \([X_3:X_2:X_1:X_0]\) where \(X_3, X_2, X_1\) and \(X_0\) are 64 bit long each.

**Step 1:** shift \(X_3\) by 63, 62 and 57-bit positions to the right. Compute the following numbers:

\[
A = X_3 \gg 63 \\
B = X_3 \gg 62 \\
C = X_3 \gg 57
\]  
(23)

**Step 2:** We XOR \(A, B,\) and \(C\) with \(X_2\). We compute a number \(D\) as follows:

\[D = X_2 \oplus A \oplus B \oplus C\]  
(24)

**Step 3:** shift \([X_3:D]\) by 1, 2 and 7 bit positions to the left. Compute the following numbers:

\[
[E_1:E_0] = [X_3 : D] \ll 1 \\
[F_1:F_0] = [X_3 : D] \ll 2 \\
[G_1:G_0] = [X_3 : D] \ll 7
\]  
(25)

**Step 4:** XOR \([E_1:E_0], [F_1:F_0],\) and \([G_1:G_0]\) with each other and \([X_3:D]\). Compute a number \([H_1:H_0]\) as follows:

\[
[H_1 : H_0] = [X_3 \oplus E_1 \oplus F_1 \oplus G_1 : D \oplus E_0 \oplus F_0 \oplus G_0]
\]  
(26)

Return \([X_1 \oplus H_1 : X_0 \oplus H_0]\).

**Bit Reflection Peculiarity of GCM**

Special peculiarity should be taken into account when implementing the GCM mode, because the standard specifies that the bits inside their 128-bit double-quad-words are reflected.

**Definition:** For a 128 bits quantity \(Q\), Reflect \((Q)\) is defined as the 128 bits quantity \(R\) whose \(i\)-th bit equal to the \((127-i)\)-th bit of \(R\), (for \(0 \leq i \leq 127\)).

This peculiarity applies to the two operands being multiplied in the finite field \(GF(2^{128})\) (defined by the specification), and also to the order of bits in the reduction polynomial, which is \([11100001:/<120 zeros>:1]\) as opposed to \([1:<120 zeros>:10000111]\).

Note that this peculiarity is not merely the difference between Little Endian and Big Endian notations.

We discuss here two approaches for handling the bit reflection peculiarity.

**Bit Reflecting the Inputs**

One approach for way handle the bit reflection peculiarity is to bit-reflect the input to the gfmul function. In GCM, one of the inputs is fixed for the whole process (it is the
hash key), it can be reflected once generated. The other inputs need to be reflected as they are produced (by the AES-CTR module).

A simple way to implement bit reflection is to use lookup tables. Ideally we want to use an 8bit → 8bit lookup table, that matches a byte to its reflected value, and then swap the order of the bytes, as required. However, a more efficient way is to implement bit reflection using a 4bit → 4bit lookup table, which can fit into a single xmm register, and to apply the PSHUFB instruction in some sophisticated way.

To bit reflect a 128bit quantity (in an xmm), we first isolate the 4bit nibbles within each byte. Then we can reflect the nibble (8 at a time) by using PSHUFB with some precomputed (constant) masks stored in two other xmm registers. We illustrate the method with the following example.

This is the contents of xmm1:

<table>
<thead>
<tr>
<th>15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x56 0xff 0x13 0x00 0x09 0x43 0x8d 0xc3 0x3a 0xfd 0x34 0x43 0x11</td>
</tr>
</tbody>
</table>

xmm1 is copied to xmm2 and the nibbles are isolated in each xmm:

xmm1 holds the lower nibbles (in each byte):

<table>
<thead>
<tr>
<th>15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x06 0x0f 0x03 0x00 0x09 0x02 0x07 0x0c 0x0a 0x0d 0x03 0x04 0x01</td>
</tr>
</tbody>
</table>

xmm2 holds the upper nibbles (in each byte):

<table>
<thead>
<tr>
<th>15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x05 0x0f 0x01 0x00 0x04 0x0b 0x04 0x01 0x08 0x0f 0x03 0x0f 0x03 0x04 0x01</td>
</tr>
</tbody>
</table>

Now let xmm3 and xmm4 hold the reflected values of the 16 possible nibbles

xmm3 holds the low reflected nibbles:

<table>
<thead>
<tr>
<th>15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0xf0 0x70 0xb0 0x30 0x0d 0x09 0x01 0x0e 0x0a 0x02 0x0c 0x04 0x08 0x00</td>
</tr>
</tbody>
</table>

xmm4 holds the high reflected nibbles:

<table>
<thead>
<tr>
<th>15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0xf0 0x70 0xb0 0x30 0x50 0x90 0x10 0xe0 0x60 0xa0 0x20 0xc0 0x40 0x80 0x00</td>
</tr>
</tbody>
</table>

Now by using xmm1 and xmm2 as the mask and xmm3 with xmm4 as the operand, one will have the reflected nibbles in the right order in xmm3 and xmm4. By adding them and using another PSHUFB to swap the order of bytes, the reflected value of the whole xmm is obtained.

This method can be used to implement any 4bit → 4bit lookup table.
Avoiding Bit Reflecting

Here, we show an alternative that helps avoiding bit reflecting the inputs. We start with the following fundamental property of carry-less multiplication:

\[
\text{reflected} \ (A) \bullet \text{reflected} \ (B) = \text{reflected} \ (A \bullet B) >> 1
\]

Using this identity, the PCLMULQDQ instruction can be used for performing multiplication in the finite field \(GF(2^{128})\) seamlessly, regardless on the representation of the input and the output operands.

Algorithm 5 outlines the required modification of the reduction algorithm that accommodates bit reflection of the inputs and the outputs in the GCM mode.

**Algorithm 5**

Denote the input operand by \([X_3:X_2:X_1:X_0]\) where \(X_3, X_2, X_1\) and \(X_0\) are 64 bit long each.

**Step 1:** compute

\[
[X_3X_2X_1X_0] = [X_3X_2X_1X_0] << 1
\]
Step 2: shift $X_0$ by 63, 62 and 57 bit positions to the left. We compute the following numbers:

$$A = X_0 << 63$$
$$B = X_0 << 62$$
$$C = X_0 << 57$$

Step 2: XOR $A$, $B$, and $C$ with $X_1$. Compute a number $D$ as follows:

$$D = X_1 \oplus A \oplus B \oplus C$$

Step 3: shift $[D:X_0]$ by 1, 2 and 7 bit positions to the right. Compute the following numbers:

$$[E_1:E_0] = [D:X_0] >> 1$$
$$[F_1:F_0] = [D:X_0] >> 2$$
$$[G_1:G_0] = [D:X_0] >> 7$$

Step 4: XOR $[E_1:E_0]$, $[F_1:F_0]$, and $[G_1:G_0]$ with each other and $[D:X_0]$. Compute a number $[H_1:H_0]$ as follows:

$$[H_1:H_0] = [D \oplus E_1 \oplus F_1 \oplus G_1 : X_0 \oplus E_0 \oplus F_0 \oplus G_0]$$

Return $[X_3 \oplus H_1 : X_2 \oplus H_0]$.

The advantage of this method, over reflecting the inputs (as shows above) is that it does not require the data to be reflected. This allows for aggregating several reductions together, for a more efficient over all implementation, as shown below.

### Implementation Using Linear Folding

Linear folding is the mathematical operation of replacing a number of most significant bits of a quantity with the product of these bits times a constant during a reduction. Folding helps with speeding up reduction because it decreases the length of the quantity which is being reduced at the expense of the number of multiplications needed. In what follows we assume that all operations that take place are carry-less, i.e., in GF(2) arithmetic.

Suppose that the quantity to be reduced can be expressed as the sum of two polynomials:

$$p(x) = (c(x) \cdot x^t + d(x)) \mod g(x)$$

Where,

1. $c(x)$ is a polynomial of degree $s-1$ with coefficients in GF(2), representing the most significant bits of the quantity to be reduced
2. $t-1$ is the length of the degree of $d(x)$
3. $g(x)$ is the irreducible polynomial defining the field (for GCM, $g = g(x) = x^{128} + x^7 + x^2 + x + 1$).
For the polynomial \( p(x) \) we write:

\[
p(x) = (c(x) \cdot x' + d(x)) \mod g(x) =
\]

\[
c(x) \cdot x' \mod g(x) + d(x) \mod g(x) =
\]

\[
(c(x) \cdot (x' \mod g(x)) + d(x)) \mod g(x)
\]

The quantity \( x' \mod g(x) \) depends only on the reduction polynomial. Hence it can be treated as a constant. Equation (34) indicates a method for performing reduction which is called linear folding and works as follows:

**Step 1:** The polynomial \( c(x) \) is multiplied carry-less with the constant \( x' \mod g(x) \).

**Step 2:** The result of the multiplication is XOR-ed with \( d(x) \).

**Step 3:** The reduction proceeds using any known technique.

The remainder from the division of \( x' \) with \( g(x) = x^{128} + x^{7} + x^{2} + x + 1 \) is the bit sequence \(<10000111: t-128 \text{ zeros}>\). Since \( t+s = 255 \) one can see that the length of the carry-less multiplication of \( c(x) \) with \( x' \mod g(x) \) is 134 and is independent of the choice of \( t \) and \( s \).

In GCM all operations are bit reflected, so folding needs to be implemented in a bit reflected manner too. The designer of an algorithm based on linear folding has several degrees of freedom that depend on the choice of \( t \) and \( s \). If the length of the folding quantity \( c(x) \) spans a single 64-bit word then the cost of multiplication with \( x' \mod g(x) \) can be potentially small, equals to 1 or 2 64-bit carry-less multiplication operations. On the other hand the cost of further reducing the given polynomial after folding may be higher.

Another issue related to the design of a folding algorithm has to do with the fact that the reflected version of \( x' \mod g(x) \) may span one or multiple words. Theoretically one can multiply \( c(x) \) not with \( x' \mod g(x) \) but with an appropriately shifted version of the bit sequence \(<11100001>\) so that the second operand of the multiplication spans exactly one 64 bit word. The result can then be corrected with further shift operations. There is one case for which the second operand of the multiplication spans one word and no further shifts are required: this is for \( t = 193 \). For this case, the subsequent reduction steps after folding requiring reducing a 193 bit quantity.

In what follows we describe four representative algorithms two for \( s = 120 \) and two for \( s = 64 \) bits. In each pair the second operand of the folding multiplication spans 1 or 2 words.

**Algorithm 6: Folding length \( s = 120 \), two multiplications version**

Denote the input operand by \([X_{3}:X_{2}:X_{1}:X_{0}]\) where \( X_{3}, X_{2}, X_{1} \) and \( X_{0} \) are 64 bit long each.

**Step 1:** Compute \([C_{1}:C_{0}] = [X_{1}:X_{0}] \AND 0x00ffffffffffffffffffffffffffffff\)

**Step 2:** Compute \([H_{2}:H_{1}:H_{0}] = [C_{1}:C_{0}] \cdot 0xe100000000000000 \) (64 bit)

**Step 3:** Shift \([H_{2}:H_{1}:H_{0}]\) by one bit position to the left

**Step 4:** XOR \([H_{2}:H_{1}:H_{0}:0]\) with \([X_{3}:X_{2}:X_{1}:X_{0}]\) and replace \([X_{3}:X_{2}:X_{1}:X_{0}]\)

**Step 5:** Replace \( X_{1} \) with the result of logical AND between \( X_{1} \) and \( 0xff000000000000000 \)
**Step 6:** Compute $A = X_1 \& (1 << 63)$, $B = X_1 << 1$, $C = (X_1 \& 0x7f00000000000000) >> 1$, $D = (X_1 \& 0x7f000000000000000) >> 6$, $E = X_1 \& 0x7f000000000000000000000000000000.$

**Step 7:** Shift $[X_3:X_2:A]$ by one bit position to the left.

Return $[X_3\oplus B\oplus C\oplus D\oplus E:X_2].$

**Algorithm 7: Folding length $s = 120$, four multiplications version**

Denote the input operand by $[X_3:X_2:X_1:X_0]$ where $X_3$, $X_2$, $X_1$ and $X_0$ are 64 bit long each.

**Step 1:** Compute $[C_1:C_0] = [X_1:X_0] \& 0x00ffffffffffffffffffffffff$

**Step 2:** Compute $[H_2:H_1:H_0] = [C_1:C_0] \& 0xc20000000000000000000000000000.$

\*\* Note: 0x1c200000000000000 is a 65-bits quantity, and therefore four multiplications are required for computing $[C_1:C_0] \& 0x1c20000000000000000000000000000.$

**Algorithm 8: Folding length $s = 64$, single multiplication version**

Denote the input operand by $[X_3:X_2:X_1:X_0]$ where $X_3$, $X_2$, $X_1$ and $X_0$ are 64 bit long each.

**Step 1:** Compute $[H_1:H_0] = X_0 \& 0xe10000000000000000$ (64 bit)

**Step 2:** Shift $[H_1:H_0]$ by one bit position to the left.

**Step 3:** XOR $[0:H_1:H_0]$ with $[X_3:X_2:X_1:X_0]$ and replace $[X_3:X_2:X_1:X_0].$

**Step 4:** Compute $A = X_1 \& (1 << 63)$, $B = X_1 << 1$, $C_1 = (X_1 \& 0x7fffffffffffffff) >> 1$, $C_0 = X_1 << 63$, $D_1 = (X_1 \& 0x7fffffffffffffff) >> 6$, $D_0 = X_1 << 58$, $E = X_1 \& 0x7fffffffffffffff.$

**Step 5:** Shift $[X_3:X_2:A]$ by one bit position to the left.

Return $[X_3\oplus B\oplus C_1\oplus D_1\oplus E:X_2\oplus D_0\oplus C_0].$

**Algorithm 9: Folding length $s = 64$, two multiplications version**
Denote the input operand by $[X_3:X_2:X_1:X_0]$ where $X_3$, $X_2$, $X_1$ and $X_0$ are 64 bit long each.

**Step 1:** Compute $[H_2:H_1:H_0] = X_0 \cdot 0x1c20000000000000000000$ (65 bit)

**Step 2:** XOR $[H_2:H_1:H_0:0]$ with $[X_3:X_2:X_1:0]$ and replace $[X_3:X_2:X_1:0]$

**Step 3:** Compute $A = X_1 \& (1 << 63)$, $B = X_1 << 1$, $C_1 = (X_1 \& 0x7fffffffffffffff) >> 1$, $C_0 = X_1 << 63$, $D_1 = (X_1 \& 0x7fffffffffffffff) >> 6$, $D_0 = X_1 << 58$, $E = X_1 \& 0x7fffffffffffffff$

**Step 4:** Shift $[X_3:X_2:A]$ by one bit position to the left

Return $[X_3 \oplus B \oplus C_1 \oplus D_1 \oplus E \cdot X_2 \oplus D_0 \oplus C_0]$.

**Aggregated Reduction Method**

This method was proposed by Krzysztof Jankowski, Pierre Laurent (see [17]). It is a way to delay the reduction step and apply the reducing to the aggregated result only once every few multiplications.

The standard Ghash formula is the following:

$$Y_i = [(X_i + Y_{i-1}) \cdot H] \mod P$$

(P = $x^{128} + x^7 + x^2 + x + 1$)

Instead, one can apply the following recursion:

$$Y_i = [(X_i + Y_{i-1}) \cdot H] \mod P$$

$$= [(X_i \cdot H) + (Y_{i-1} \cdot H)] \mod P$$

$$= [(X_i \cdot H) + (X_{i-1} + Y_{i-2}) \cdot H^2] \mod P$$

$$= [(X_i \cdot H) + (X_{i-1} \cdot H^2) + (X_{i-2} + Y_{i-3}) \cdot H^3] \mod P$$

$$= [(X_i \cdot H) + (X_{i-1} \cdot H^2) + (X_{i-2} \cdot H^3) + (X_{i-3} + Y_{i-4}) \cdot H^4] \mod P$$

This can be further expanded to any depth. The only overhead in this computation is the need to calculate the powers of $H \mod P$ in advance, but the gain is that reduction is required only once in a few blocks. As can be appreciated now, the use of the identity (27) is advantageous because the data (from the AES-CTR) does not need to be manipulated, as would be the case if we choose the bit reflect method.

A good choice, which we adopt here, is to compute one reduction every 4 blocks.

**Code Examples: Ghash Computation**

Figures 5-8 are assembly and C code examples for implementing the Galois Field multiplication portion of GCM, using some combinations of the algorithms described in the section "Efficient Algorithms for Computing GCM".

These codes implement the "gfmul" function which is, in the subsequent chapter, integrated into the full AES-GCM code.
Figures 5-6 implement the same algorithms – one example in C and the other example in assembly (AT&T syntax). The assembly code example can be compiled from an assembly file, using the gcc compiler, with -maes and -msse4 flags.

The code in Figure 7 implements a different selection of algorithms.

The code in Figure 8 implements the Aggregated Reduction Method.

**Figure 5. Code Sample - Performing Ghash Using Algorithms 1 and 5 (C)**

```c
#include <wmmintrin.h>
#include <emmintrin.h>
#include <smmintrin.h>

void gfmul (__m128i a, __m128i b, __m128i *res){
    __m128i tmp0, tmp1, tmp2, tmp3, tmp4, tmp5, tmp6, tmp7, tmp8, tmp9;
    tmp3 = _mm_clmulepi64_si128(a, b, 0x00);
    tmp4 = _mm_clmulepi64_si128(a, b, 0x10);
    tmp5 = _mm_clmulepi64_si128(a, b, 0x01);
    tmp6 = _mm_clmulepi64_si128(a, b, 0x11);
    tmp4 = _mm_xor_si128(tmp4, tmp5);
    tmp5 = _mm_slli_epi32(tmp4, 31);
    tmp4 = _mm_slli_epi32(tmp4, 31);
    tmp9 = _mm_srli_epi32(tmp3, 12);
    tmp8 = _mm_srli_epi32(tmp8, 4);
    tmp7 = _mm_srli_epi32(tmp7, 4);
    tmp3 = _mm_or_si128(tmp3, tmp7);
    tmp6 = _mm_or_si128(tmp6, tmp8);
    tmp6 = _mm_or_si128(tmp6, tmp9);
    tmp7 = _mm_slli_epi32(tmp3, 31);
    tmp8 = _mm_slli_epi32(tmp3, 30);
    tmp9 = _mm_slli_epi32(tmp3, 25);
    tmp7 = _mm_xor_si128(tmp7, tmp8);
    tmp7 = _mm_xor_si128(tmp7, tmp9);
    tmp8 = _mm_xor_si128(tmp8, tmp7);
    tmp7 = _mm_xor_si128(tmp7, tmp2);
    tmp5 = _mm_srli_epi32(tmp5, 7);
    tmp2 = _mm_srli_epi32(tmp3, 1);
    tmp4 = _mm_srli_epi32(tmp3, 2);
    tmp5 = _mm_srli_epi32(tmp3, 7);
    tmp2 = _mm_xor_si128(tmp2, tmp4);
    tmp2 = _mm_xor_si128(tmp2, tmp5);
    tmp2 = _mm_xor_si128(tmp2, tmp8);
    tmp3 = _mm_xor_si128(tmp3, tmp2);
    *res = tmp3;
}
```

```assembly

Code Examples: AES128-GCM

This chapter provides several code examples for implementing AES-GCM using PCLMULQDQ and the AES instructions (see [16] for details). We demonstrate here AES128 in GCM mode. The extension to AES192 and AES256 in GCM mode is straightforward (implementation of AES192/AES256 CTR is given in [16]). One of the AES-CTR implementations (Figure 12) uses the technique of processing several (four in this case) blocks in parallel. Reference [17] described the motivation and benefits of such parallelization techniques for AES in any parallel modes of operation.

How to Use the Code Examples

In the following, we provide three possible options for using the provided code examples.

For AES-GCM, using the simplest method (one blocks at a time): save Figure 5 as gfmul.c or, alternatively, Figure 6 as gfmul.s. Save Figure 9 as aes_gcm.c.

For AES-GCM, using the reflected variation, use Figure 7 for gfmul.c, and Figure 10 for aes_gcm.c.

For AES-GCM, using the parallelized method, save Figure 5 and Figure 8 together as gfmul.c, save Figure 11 as aes_gcm.c.

For all methods, save Figure 12 as key_schedule.c and Figure 13 as gcm_main.c.

For Intel Compiler (icc) users: the files can be compiled using the compilation line:

```
icc gcm.c key_schedule.c gcm_main.c gfmul.c -o AES128_GCM -DTEST[1-6]
```

For gcc users: the files can be compiled using the compilation line

```
gcc -maes -msse4 key_schedule.c gcm_main.c gfmul.c -o AES128_GCM -DTEST[1-6]
```

-DTEST[1-6] selects one of the 6 AES GCM tests that are included in the main function. Running the resulting executable (AES128_GCM) would give the respective printout, as described in the section "Code Outputs" below (e.g., -DTEST1 selects test number 1). The test vectors were taken from the specification document:

The code can be run even without a processor based on Intel microarchitecture codename Westmere, using Intel® Software Development Emulator (Intel® SDE), which can be downloaded from http://www.intel.com/software/sde.
AES-GCM Code Examples

PCLMULQDQ and GFMUL Test Vectors

This chapter provides a few test vectors. “Little Endian” notation is used unless specified otherwise.

PCLMULQDQ Test Vectors

The following first 4 test vectors have the same xmm1 and xmm2 input, and vary only in the value of the immediate byte. This way, the result of all of the four combinations, High/Low from xmm1 and xmm2, are generates. Only bits [4] and [0] of the immediate byte are used for selecting the multiplicands.

Input to the PCLMULQDQ instruction
xmm1 = 7b5b54657374566563746f725d53475d
xmm2 = 4869285368617925b477565726f6e5d

The corresponding 64-bit Low/High halves are
xmm1High = 7b5b54657374566563746f725d53475d
xmm1Low = 63746f725d53475d
xmm2High = 4869285368617925b477565726f6e5d
xmm2Low = 5b477565726f6e5d

Test Vector 1:
immediate = 0x00; carry-less multiply xmm2Low by xmm1Low
PCLMULQDQ result = 1d4d84c85c3440c0929633d5d3ef0451
**Test Vector 2:**
immediate = 0x10; carry-less multiply xmm2High by xmm1Low
PCLMULQDQ result = 1bd17c8d556ab5a17fa540ac2a281315

**Test Vector 3:**
immediate = 0x01; carry-less multiply xmm2Low by xmm1High
PCLMULQDQ result = 1a2bf6db3a30862fbabf262df4b7d5c9

**Test Vector 4:**
immediate = 0x11; carry-less multiply xmm2High by xmm1High
PCLMULQDQ result = 1d1e1f2c592e7c45d66ee03e410fd4ed

**Test Vector 5:**
xmm1 = 00000000000000008000000000000000
xmm2 = 00000000000000008000000000000000
immediate = 0x00
PCLMULQDQ result = 40000000000000000000000000000000

**Multiplication in GF(2^{128}) Defined by the Polynomial x^{128} + x^7 + x^2 + x + 1**

\[ a = 0x7b5b54657374566563746f725d53475d \]
\[ b = 0x48692853686179295b477565726f6e5d \]
\[ \text{GFMUL128} \ (a, b) = 0x40229a09a5ed12e7e4e10da323506d2 \]
\( \text{(GFMUL128} \ (a, b) \text{ is the multiplication results of } a \text{ and } b, \text{ in GF(2^{128}) defined by the reduction polynomial } g = g(x) = x^{128} + x^7 + x^2 + x + 1) \)

**GCM Test Vector**

The following test vector takes into account the special peculiarity of GCM which specifies that the bits of the input operands (data and hash keys) and the output operand should be reflected

**Data:** 0x952b2a56a5604ac0b32b6656a05b40b6
**Hash Key:** 0xdfa6bf4ded81db03ffcaff95f830f061
**Multiplication Result:** 0xda53eb0ad2c55bb64fc4802cc3feda60

**Explanation:** For a 128 bits quantity X, Reflect (X) is defined as the 128 bits quantity Y whose i-th bit equal to the (127-i)-th bit of X, (for 0 ≤ i ≤ 127).

If
\[ A = 0x952b2a56a5604ac0b32b6656a05b40b6 \]
\[ B = 0xdfa6bf4ded81db03ffcaff95f830f061 \]

And,
\[ C = \text{Reflect} \ (A) \times \text{Reflect} \ (B) \]
\( \text{("*" is in GF(2^{128}) defined by the polynomial } g = g(x) = x^{128} + x^7 + x^2 + x + 1) \)
Then
Reflect (A) = 0x6d02da056a66d4cd035206a56a54d4a9
Reflect (B) = 0x860f0c1fa9ff53ffc0db81b7b2fd65fb
C = 0x65B7FC3340123F26DDAA34B50D7CA5B

Finally,
Reflect (C) = 0xda53eb0ad2c5bb64fc4802cc3fed6a0

Which is the "Multiplication Result" obtained above.

Performance

This chapter provides the performance numbers of the code examples which were given above, and, for comparison, the performance of code that does not use Intel AES New Instructions / PCLMULQDQ instruction (running on the same platform).

The experiments were carried out on a processor based on Intel microarchitecture codename Westmere running at 2.67 GHz. The system was run with Intel® Turbo Boost Technology, Intel® Hyper-Threading Technology, and Enhanced Intel Speedstep® Technology disabled, and no X server and no network daemon running. The operating system was Linux (OpenSuse 11.1 64 bits).

The C code parts were compiled using icc version 11.0 with the –O3 flag. For the AES-GCM, the key was pre-expanded, and the key expansion overhead was not counted. Table 1, below, provides performance numbers for three buffer sizes.

The performance results are summarized in Table 1. The top part of Table 1 shows several implementations of AES-GCM, using the algorithms which were provided in the paper. The bottom part of Table 1 shows the performance of code that does not use the PCLMULQDQ and the Intel AES New Instructions.

**Table 1. The Performance of AES-128 in GCM Mode (on a processor based on Intel microarchitecture codename Westmere)**

(*): The code was downloaded from [http://src.opensolaris.org/source/xref/onnv/onnv-gate/usr/src/common/crypto/modes/gcm.c#46](http://src.opensolaris.org/source/xref/onnv/onnv-gate/usr/src/common/crypto/modes/gcm.c#46) (on September, 2009)

(**): The code was downloaded from [http://gladman.plushost.co.uk/oldsite/AES/index.php](http://gladman.plushost.co.uk/oldsite/AES/index.php) (July 2009)

**Discussion**

The significant speedup gained from using the PCLMULQDQ instruction and the Intel AES New Instructions, together with the proposed algorithms is evident.

For the cases where the GHASH is computed one block at a time, Table 1 shows that bit-reflecting the input it faster than the shift-by-one method (Algorithm 5). However, the picture changes when the GHASH is aggregated and computed only once per four (or more) blocks at a time. Then, the shift-by-one method allows for processing the input data (the ciphertext from the AES-CTR part of the algorithm) without bit-reflection, and the reduction modulo $x^{128} + x^7 + x^2 + x + 1$ occurs less frequently. In this case, the aggregated reduction method outperforms the other approaches, achieving performance of 3.54 Cycles/Byte (for long buffers). Note that in CTR mode...
the counter is encrypted (rather than the data). Therefore, the number of blocks which are processed in parallel, and the number of blocks which are aggregated before computing a reduction, is an implementation preference.

Table 1 also shows that performance improved with longer buffers. This is due to the fact the overhead for the initialization of the H value \((s)\), and for the CTR mode is amortized over a larger chunk of data. For 4K buffer (and longer), the fastest implementation performs is more than 6 times faster than the existing implementations that use lookup tables.

## Summary

This paper presented Intel’s, new instruction, namely PCLMULQDQ, that performs carry-less multiplication of two 64-bit operands. We provided information on using PCLMULQDQ for computing the Galois Hash portion of the Galois Counter Mode. We also detailed several methods for using PCLMULQDQ and Intel AES New Instructions in order to implement AES-GCM. The reported performance numbers show significant speedup in AES-GCM, compared lookup tables based software implementations.

About the Authors

Shay Gueron is an Intel Principal Engineer. He is the security architect of the CPU Architecture Department in the Mobility Group, at the Israel Development Center. His interests include applied security, cryptography, and algorithms. He holds a Ph.D. degree in applied mathematics from Technion—Israel Institute of Technology. He is also an Associate Professor at the Department of Mathematics of the Faculty of Science at the University of Haifa, in Israel.

Michael E. Kounavis is a Senior Research Scientist at Intel Corporation. He joined Intel in 2003. Since then he has worked on developing novel algorithms and solutions for line rate packet processing, security and data integrity. His current research focuses on accelerating cryptographic algorithms and protocols. Michael has co-invented the CRC32, PCLMULQDQ instruction, and the Intel AES New Instructions for the Intel® microarchitecture codename Nehalem and Intel® microarchitecture codename Westmere, and was a co-recipient of an Intel Achievement award for the AES work, in 2008. Prior to joining Intel, he worked on programming network architectures at Columbia University, where he also received a Ph.D degree in 2004.
